#### ACKNOWLEDGEMENTS

We are indebted to Dr. Bruce J. Blanchard, NASA-Goddard for his help. He very generously shared the edited data sets then separately under evaluation by Dr. Sid Theis and Dr. Wes Rosenthal at Texas A & M University, Remote Sensing Center (TAMU). Dr. Al Chang, NASA-Goddard and Ms. Peggy O'Neal, NASA-Goddard provided both technical advice and emotional support via their noteworthy interest. Ms. Cheryl Jones and Dr. Richard Newton, TAMU, provided insight into the data set collection characteristics. Mr. Tim Minor (GRSU-UCSB) effected continuation of project management upon the completion of Mr. Rob Lees' thesis.

#### MULTI-SENSOR DETERMINATION OF SOIL MOISTURE

#### I. Introduction

The Guymon soil moisture data set which was the source for the analyses reported by Hajic (1981) was revised.\* This revised Guymon data and the Dalhart soil moisture data collected on August 14, 16, and 18, 1980 have each been grouped into four field cover types for statistical analysis. The Guymon data is grouped as bare, alfalfa, mile with rows perpendicular to the field of view, and mile viewed parallel to the field of view. The Dalhart data is grouped as bare combo (including bare stubble, pasture, and millet), stubble (including vegetated, disked, wheat and mulched stubble), disked stubble, and corn fields. Tables 1A and 1B show the data collection fields and dates for each cover type in the Guymon and Dalhart data sets respectively. Tables 2A and 2B summarize the variables and associated symbols used in the analysis. Prefix and suffix symbols are explained and data set names identified.

The organization of the analysis summary is parametric in field cover type with the same types of analyses performed for each cover type. It is preceded by an overview with summery graphs which combine selected analyses to compare the effects of field cover. The analysis for each of the cover types is presented principally in the form of graphs and tables with only brief commentary since in-depth examination of these results has not yet been done.

The remainder of the report consists of tables of elementary statistics, correlation matrices, and single variable regressions. A concluding chapter summarizes selected eigenvector and factor analyses. The elementary

Per revisions by TAMU, Spring 1981.

statistics provide the mean and standard derivation of all variables. Correlation matrices were determined for high correlating sensors and for correlation between soil depths. The highest correlating sensor types for SMO2 (Guymon) and FLDO2 (Dalhart) are summarized via tables of the intercepts and regression coefficients. These variables represent the values of the flight line volumetric soil moisture in the 0-2 cm depth layer and the field average volumetric soil moisture in 0-2 cm depth layer respectively.

#### 2. Overview

This overview is arranged in four parts to show the effect of cover types. These include the raw data, correlation coefficients, single variable regressions, and stepwise regressions as derived from the highest correlating variables. A critical and intensive examination of all these preliminary reports remains to be done.

### 2.1 Cover Type Comparisons

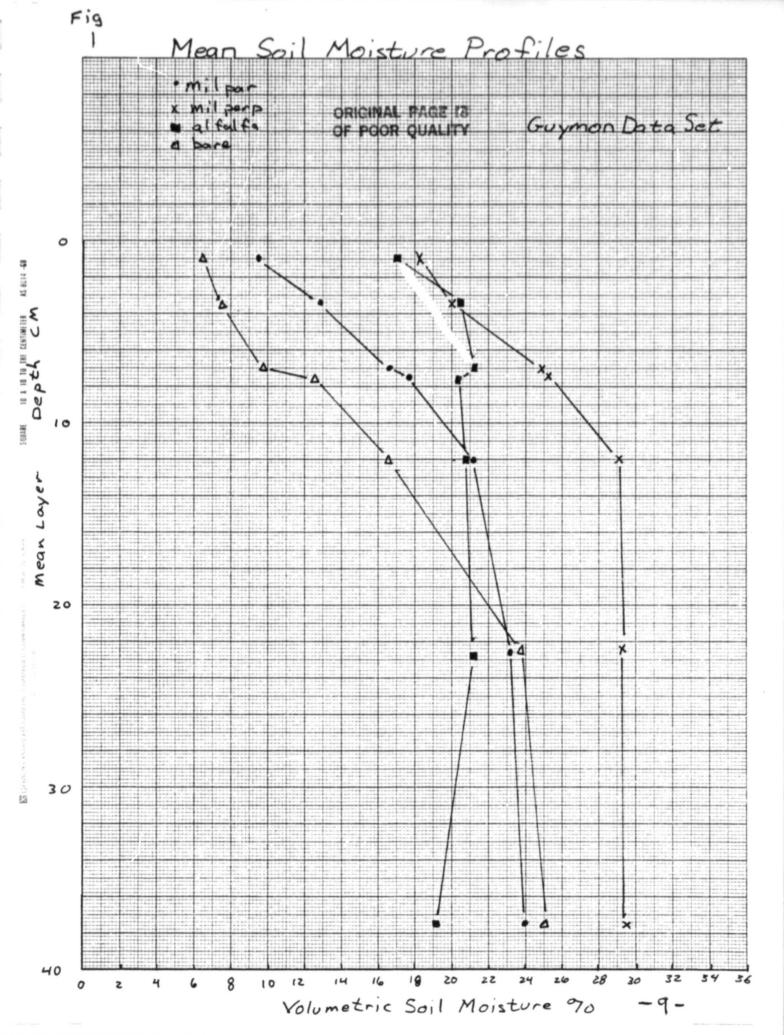

A large number of variables are being compared in this analysis. Explication of the effects of single variable changes in the analysis is complicated by the fact that comparisons of sensor types and responses contain the convolved effects of multi-variable changes soil moisture profiles, cover types and soil textures. In some instances, the effect of a single variable change is approximated via the regression equations.

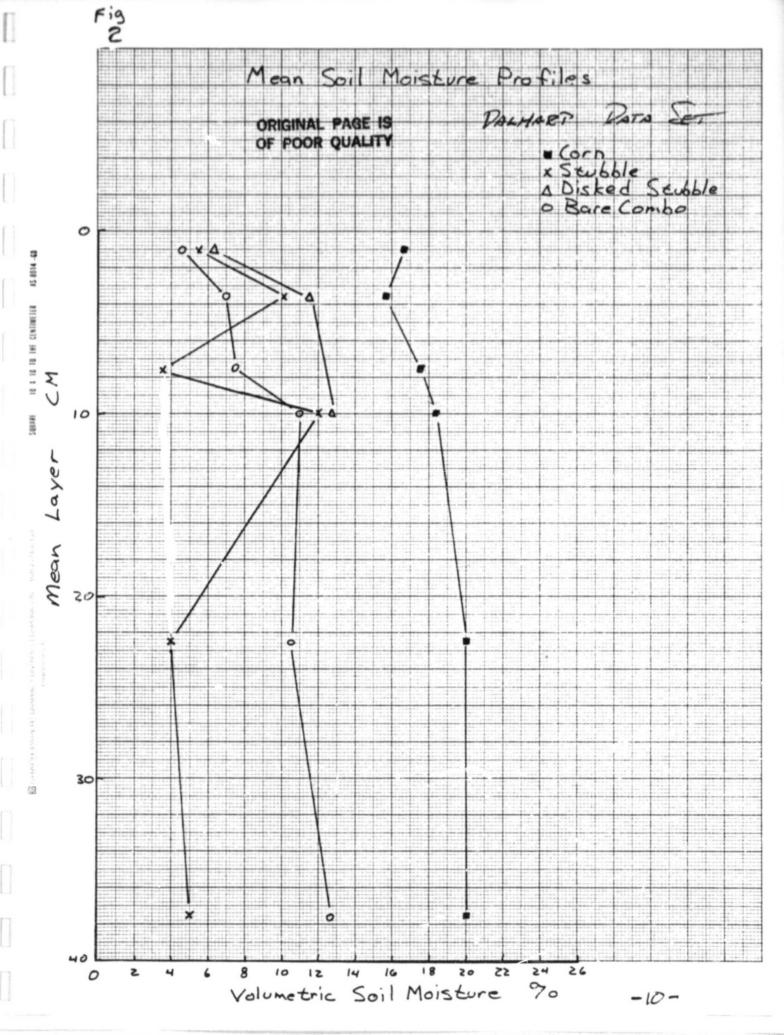

#### 2.1.1 Raw Data

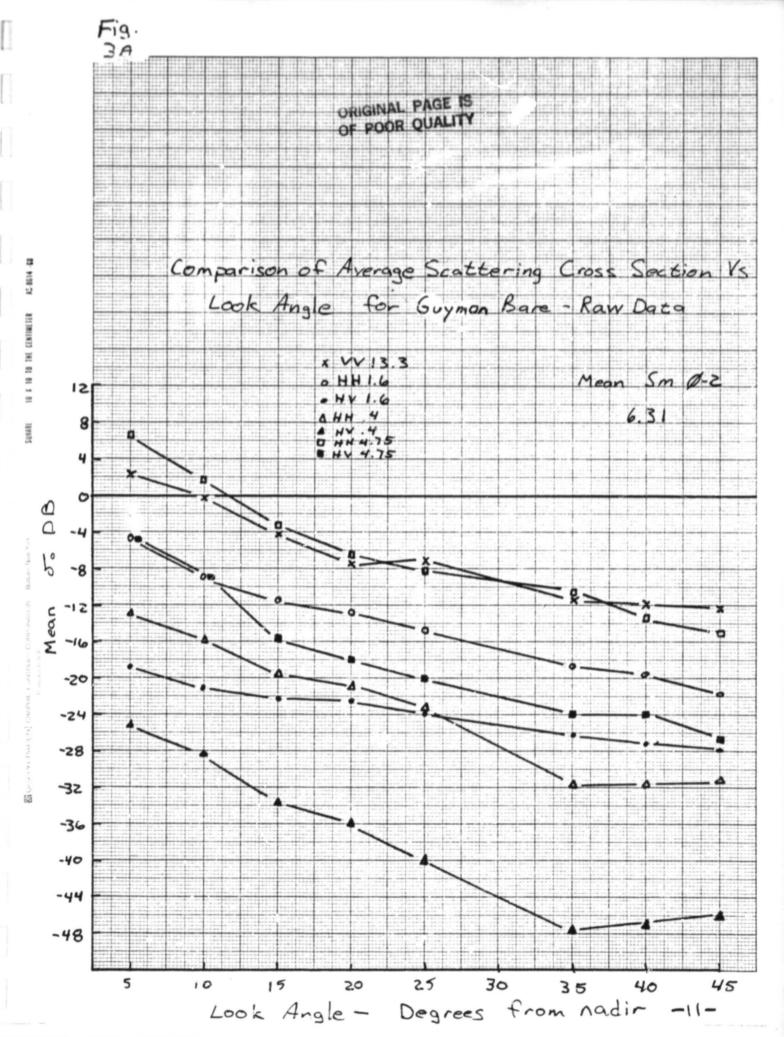

Consider first that determining the effects of cover types is difficult due to the fact that the sets of fields have significantly different moisture profiles. Figures 1 and 2 show the mean values of each layer plotted at the mean depth of each soil sample layer. Thus the mean scattering cross sections, Figures 3 and 4, incorporate these effects as do the plan view direction modulation for the milo fields (viewed parallel or perpendicular to the rows), in Figure 3E.

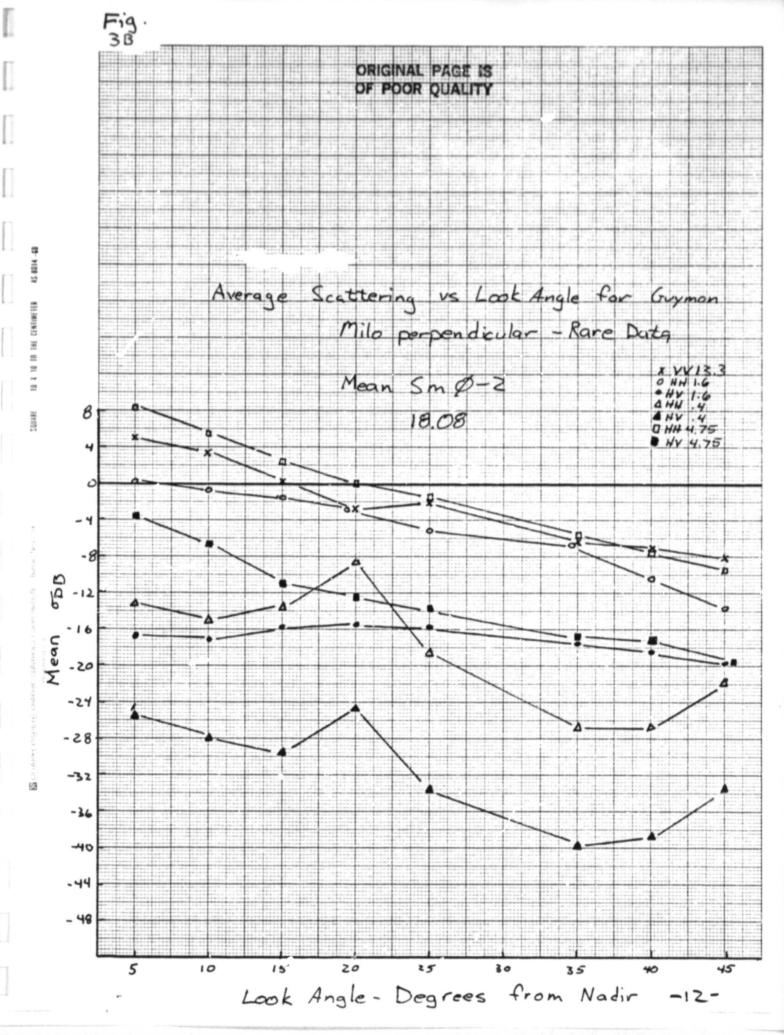

Soil textures also differ from field to field. Tables 3 and 4 briefly show the variation in textures of the sampled fields. Lees (1981) discussed the analysis of the soil texture vs soil moisture of the Guymon and Dalhart data sets, therefore these tables have been included here for comparison only.

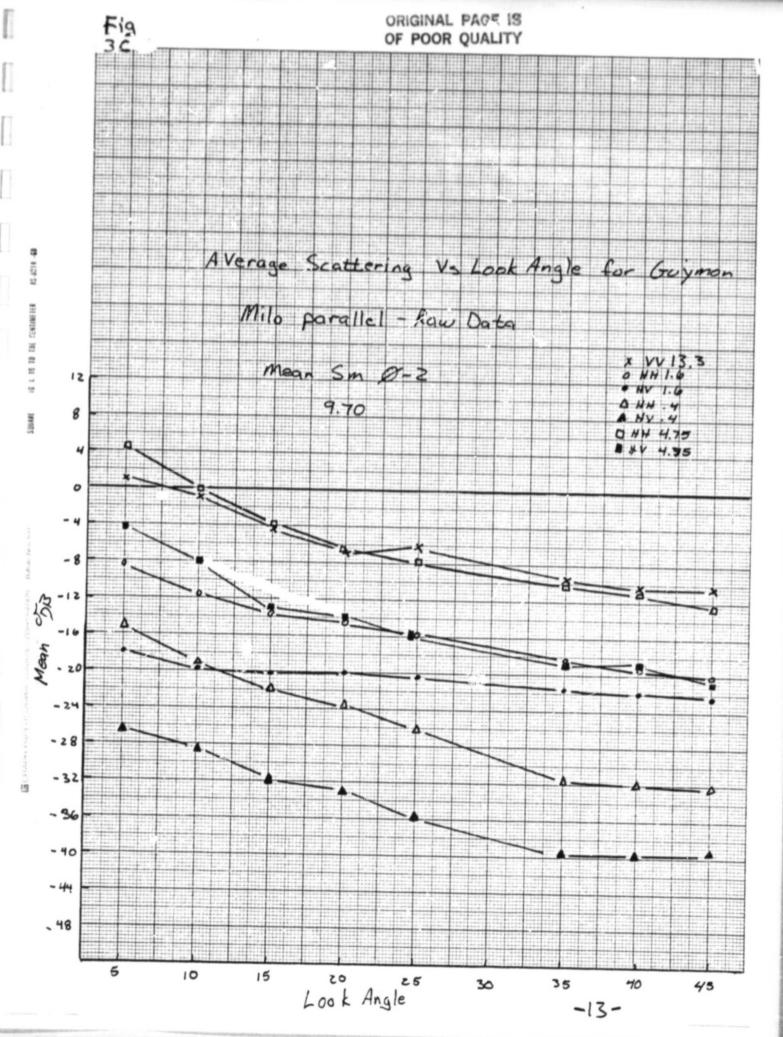

Noteworthy is relatively smaller excursions in mean scattering cross-section of the MV 1.6 Ghz sensor ( compared to all other sensors and polarizations) as look angle is varied. This is particularly evident in the Guymon data sets for all cover types (Figures 3A - 3D). It is significantly less evident in the Dalhart data sets (Figures 4A - 4D).

#### 2.1.2 Correlation Coefficients

The effects of scatterometer look angle, frequency, and polarization on correlation with volumetric soil moisture in the 0-2 cm layer is shown in Figures 5 and 8. Significant is the relatively constant correlation of the HV 1.6 Ghz sensor channel for look angles of  $\geq 10^{\circ}$  in the Guymon bare field data set. In comparison the HV 4.75 Ghz channel for look angles of  $\geq 10^{\circ}$  in the Dalhart bare field data set has relatively constant but lower correlation coefficients. For the latter set the HH 4.75 Ghz shows no correlation.

Note also the great disparity in the correlation results of the .4 Ghz HH and HV sensor. The Guymon bare field data shows increasing negative correlations for the HH polarization (with increasing look angle) and essentially no correlation for the HV data. In contrast, the .4 Ghz HV sensor ranks as one of the highest in (somewhat constant) correlation for the Dalhart bare (combo) field data. The .4 Ghz HH data shows a similar and somewhat lower correlation trend. These discrepancies have not been explained.

Throughout the data analysis relatively little difference in results were found in comparisons of the field average (FLD) vs. line (SM) soil moisture sets - most analysis results are also similar to those reported last year to later data editing (Hajic, 1981).

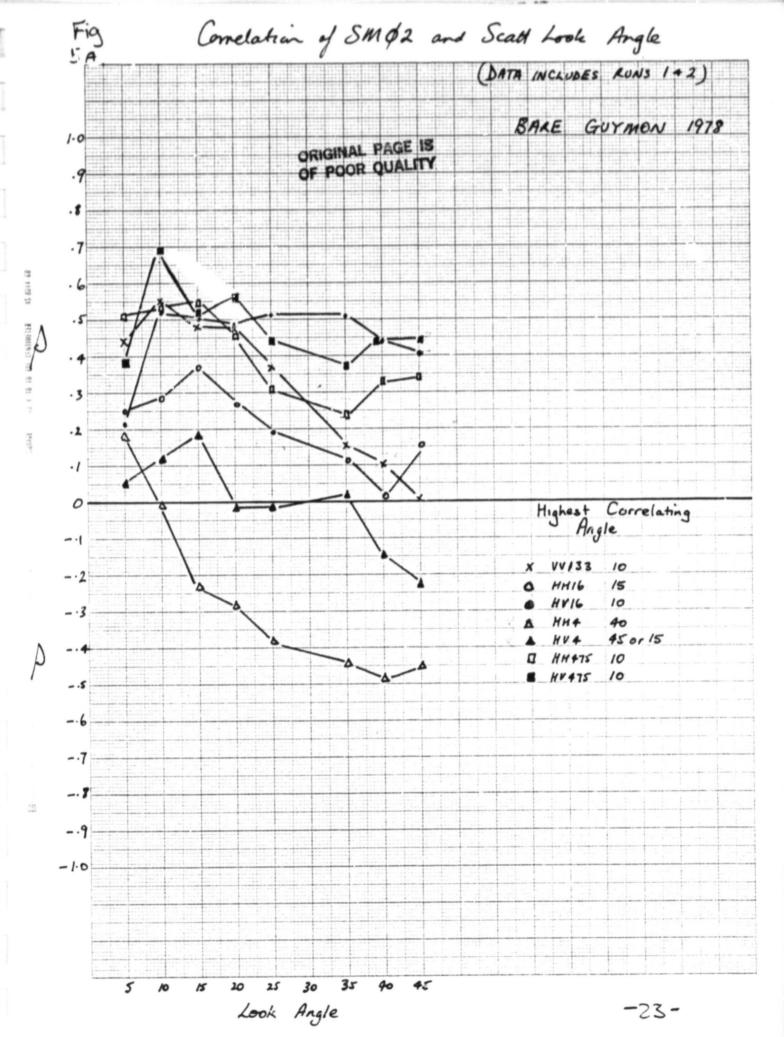

Figures 6 and 9 show correlations with passive microwave sensors.

Figure 7 similarly shows the correlations for the Modular Multispectral

Scanner (Guymon) and Figure 10 for the Thematic Mapper Simulator (Dalhart).

A comparison of the coefficients of correlation of the sensor responses with the volumetric soil moisture measured at progressively deeper layers is shown in Figures 11, 12, 13, and 14. The depth is plotted at the midway point for the layers 0-2, 2-5, 5-9, and 9-15 cm for Guymon with 0-2, 2-5,

and 9-15 cm for Dalhart. As a reference, the correlation of the soil moisture at each depth with that in the top 0-2 cm is shown. Since the latter is shown to remain relatively high and almost constant for all cover types, except bare, no conclusions can be readily reached regarding the distribution of depth to the sensor response. The generally high correlating scatterometer look angles of less than 25 degrees are shown. This is to show the significant effect of a relatively small change in look angle on the correlation.

## 2.13 Single Variable Regressions

A comparison of the linear regressions with SMO2 and FLDO2 as the dependent variable parametric in cover types is shown in Figures 15 and 16. The scatterometer regressions are for look angles less than 25 degrees as the independent variable.

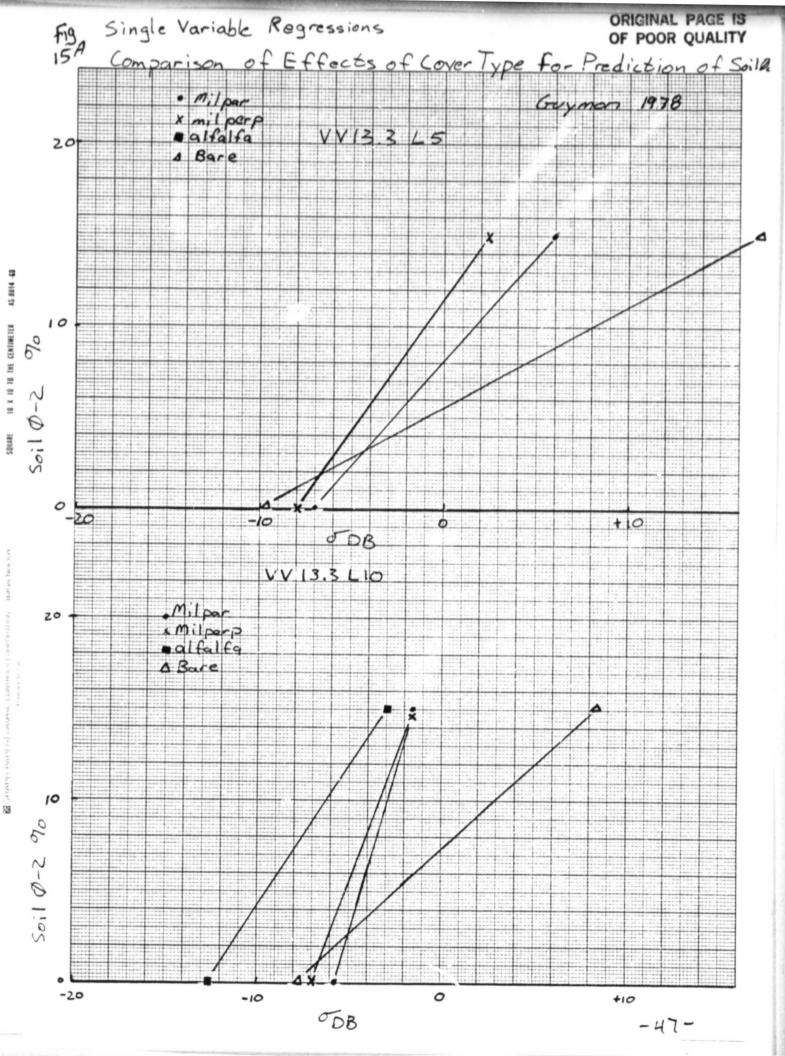

The standard error of estimate of SMO2 and FLDO2 for the scatterometers and passive microwave sensors are shown in Figures 17 and 18. Note that for the Guymon data the highest standard errors are recorded by the cross-polarized scatterometers and specifically for the alfalfa fields. The bare fields evidenced the lowest standard errors. For the Dalhart data the parallel-polarized scatterometers tend to follow their crosspolarized counterparts, especially in the higher look angles. The combined stubble fields tend to show the lower standard errors and corn the higher standard errors. A summary of the complete set of one independent variable regression constants showing effects of cover and look angle is summarized in Figures 19 and 20. Note the typical progressions up and down the line as the look angle is varied for each cover type. The Daihart data is particularly interesting in that the majority of cover types with the exception of corn, tend to parallel each other through the various look angles. The graphs also tend to lay close to a linear projection through the axis (Figure 20). This is true for all the Dalhart scatterometers and the passive microwave sensors excluding both the HH and HV 4.75 scatterometers in Figures 20F and 20G. The latter sensors are very unique in appearing to be relatively insensitive to a change in look angle.

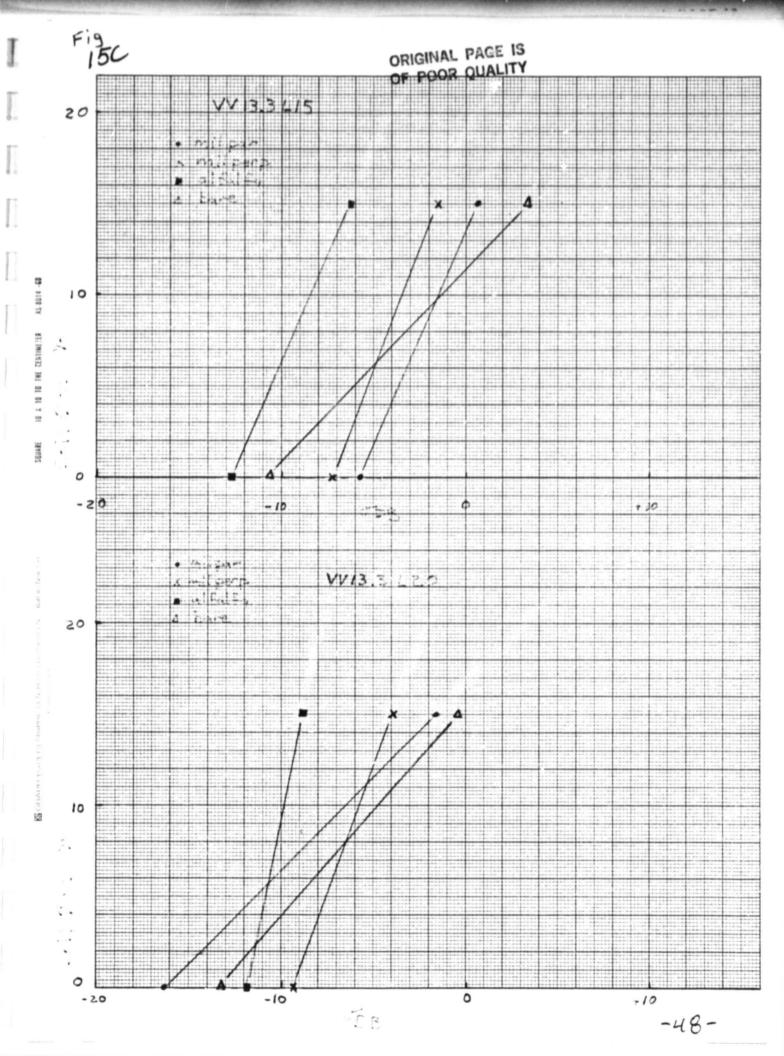

The calculated sensor responses necessary to 'predict' soil moisture values of SM/FLDO2 = 0%, 5%, and 15% are shown in Figures 21-24 (Guymon) and Figures 25-28 (Dalhart). Note that such calculation does not adjust

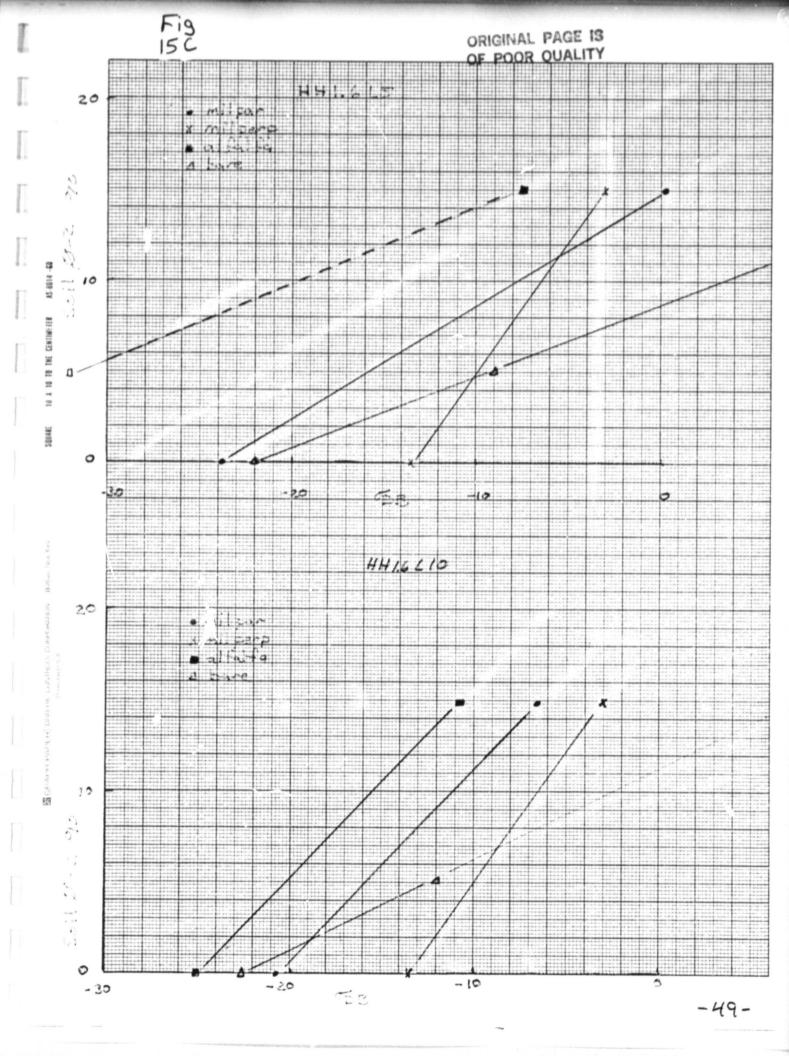

the soil moisture depth-profiles to conform to a common, single profile for each cover group. Thus direct comparisons to determine the effect of single variable changes are still confounded by such convolved and different effects. Notice that for the bare and milo par fields the required HV 1.6 scattering coefficients are within about 1 dB. but in general they both fluctuate independently of the other cover types, moisture percentages, and sensors. The other covers, alfalfa and milo perp., act independently by sensor, however, they remain relatively constant throughout the range of moisture percentages. The required HV 4.75 scatterometer responses appear to be the most similar to each other and consistent with varying look angle as the effect of each cover in Guymon data is examined.

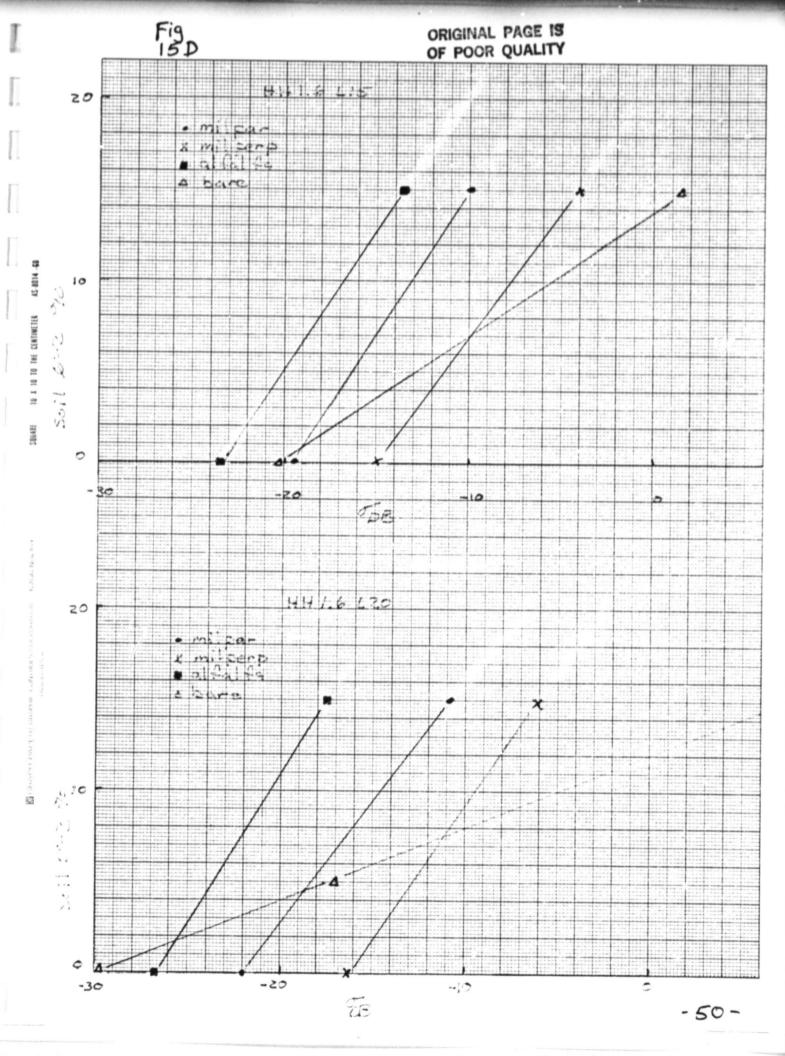

The Dalhart data analysis of the corn fields (Figures 25A-28) shows the effects of possibly, the 'psuedo' coherent backscatter caused by the vegetation. This is also evidenced in the 'oscillatory' nature of the variable trajectories (in factor space) for the 1.6 Ghz HH and HV sensors (see Figure 37). In sharp contrast the 4.75 Ghz HH and HV sensors remain in a relatively constant (factor space) position.

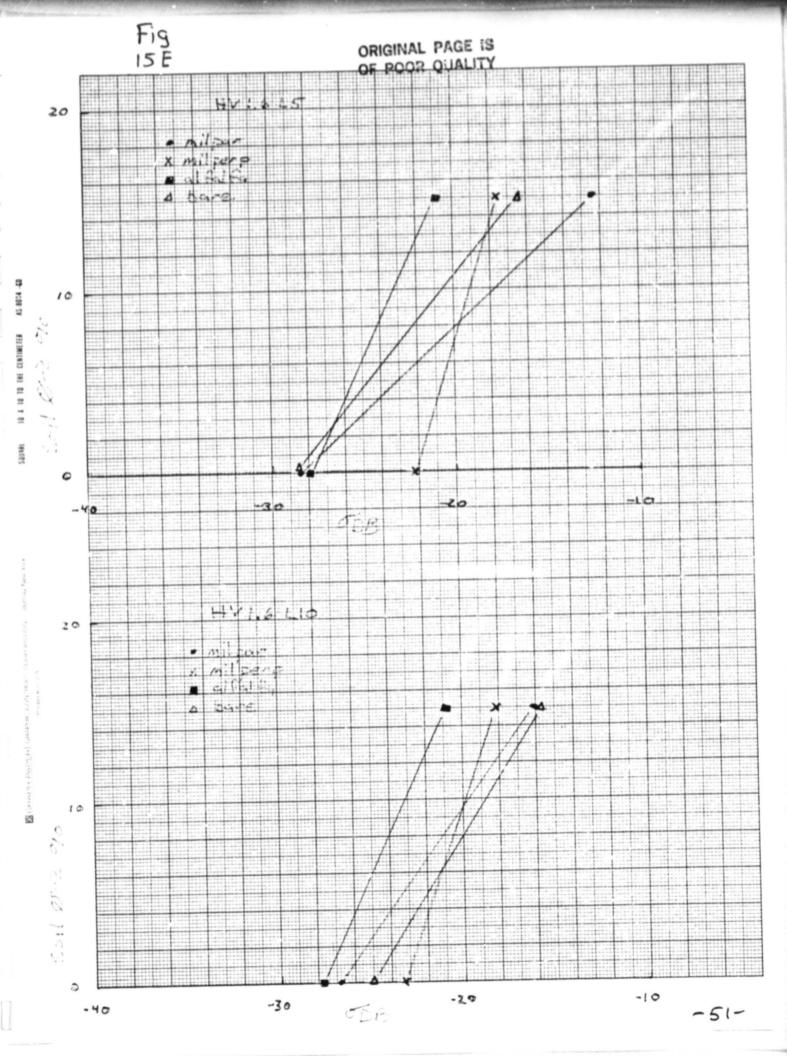

Note particularly the nature of the 'required responses' to predict a given soil moisture vis a vis the curves for the other, less vegetated covers.

Regression Coefficient

#### 2.14 Stepwise Regressions

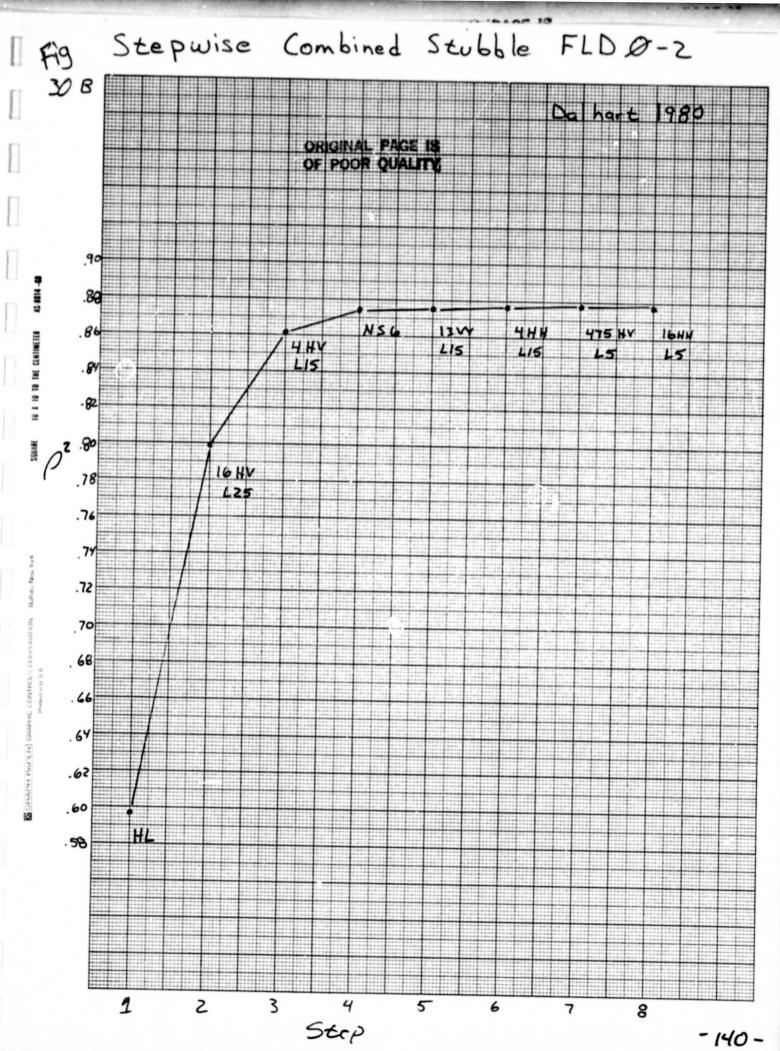

An overview of the stepwise regressions is presented parametric in cover types (Figures 29 and 30). These are summarized in the sequence of the variable selected and the combined correlation coefficient. The various steps reflect the maximum correlation coefficients successively as highest correlating sets of variables were determined. The regressions were determined primarily for the SMO2 (Guymon) and FLD 02. (Dalhart) as the dependent variables. The highest correlating sensor channels for each sensor type were used as the source of independent variables.

The microwave radiometer (HC in Guymon; HL in Dalhart) consistently appears in the stepwise regressions for all cover types. Similarly evident are the 13.3 Ghz VV and 1.6 Ghz HV sensors. Note that the greatest step increases of correlation for added sensors occurs for the Guymon milo parallel (but not perpendicular) data and the Dalhart stubble data.

#### III. Eigenvector and Factor Analysis

The utility of eigenvector and factor analyses was briefly explored. An important issue was examining the sense of the general and comparative movements (or trajectories) of the soil moisture variable (as affected by measurement depth) and for the scatterometers (as influenced by increasing look angle from nadir and polarization). Ideally, if the soil moisture was constant for all depths, perhaps the comparative trajectories of depth, look angle, and polarization would be suggestive of types of sensor kernels or weighting functions useful for a subsequent study of deconvolution of the soil moisture sensor measurements.

Obviously a significant problem is the extremely small sample size vis a vis the number of variables and the consequent constraints placed on such a general statistical study. The utility of factor analysis has been both advocated (cf. Vande Geer, 1971; Lawley and Maxwell, 1963) and maligned (Armstrong, 1967) at various times. Recently it was employed as an interpretation help (in concert with unsupervised clustering) for the complex radiometric and ground truth data in the microwave remote sensing of snow (Mätzler et al., 1982). Frank (1979) also used it with clustering in a categorization of watershed units.

Additional considerations on the validity and use of the factor graphs includes:

- o The potential of exploratory insight into the interactions\* concealed within the data set;
- o The reasonable relatedness of the factor displays via a rescaling and normalization of the factor axes to the eigenvectors. For example, a comparative display of the eigenvectors and factors of selected variables from the Guymon Bare and Dalhart Stubble data sets (Factor BX and Factor SX runs) are shown in Figures 312 (p.194) and 362 (p.221).

<sup>\*</sup>Note, for example in Figure 37, the 'oscillatory' variable-trajectory behavior (in factor space) of the 1.6 HH and 1.6 HV sensors for the Dalhart corn data and the contrasting, stationary trajectories for the 4.75 Ghz HH and HV sensors.

o The 'parent' eigenvector transformation has found very legitimate and extensive use in similar form in image enhancements for geophysical prospecting (Moik, 1981) and for crop phenology trajectories for multidate image analysis (Hallada, 1980).

An overview of the data sets analyzed herein and the cumulative fraction of variance represented by the first four selected eigenvectors is shown in Table 33. Similarly the cumulative fraction of the four rotated factors is included. This table overviews the second major run of eigenvector and factor analyses. It was preceded by the initial runs summarized in Table 34 which included all sensor variables. Table 33 and the factor graphs included herein have excluded the .4 Ghz HV and HH sensor outputs. This was done for two reasons: the correlation graphs shown earlier summarized the rather 'unusual' correlation behavior of the .4 Ghz data as a function of increasing look angle; hence further statistical studies based on such correlations would be suspect. Additionally, the large number of data points on the factor graphs 'begs' for some relief (especially in a format not showing the multicolor curves of the original).

Briefly the data transformations were effected via the SAS factor procedure. The sequence is similar to that cited by Matzler et al. (1982):

- o eigenvectors of the correlation matrix were determined;
- o the eigenvectors were stretched via a coodinate frame weighting that yields factor axes;
- o the centered data vectors were transformed into factor space via projections on the factor axes.

The sequence of data sets summarized by the factor graphs follows that of the preceding sections is 2

Corn

\*Note: When the letter X follows it designates data sets from which the .4 HV and .4 HH scatterometer data has been removed.

For each field cover type, the graph and table sequence is the following:

- o Trajec@ry plots (lines and data points) of highest two variance axes;
- Trajectory data points of third and fourth-ranked variance axes;
- o Table of the four-factor loadings after rotation which produced the above graphs and the orthogonal transformation matrix:
- o Table of four-factor loadings prior to rotation; and,
- o Table of the four eigenvectors from which the factors were stretched and weighted.
